Development of Urinary Bladder

Development of Urinary Bladder

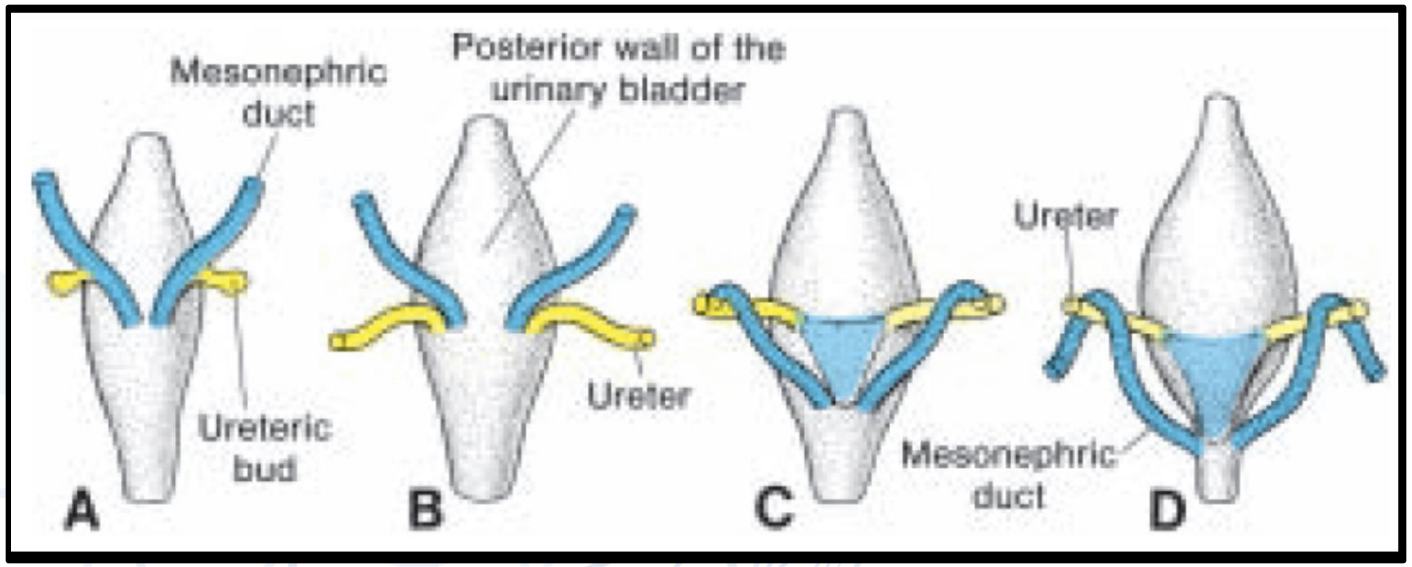

Development of Urinary Bladder

- **The trigone** develops from absorbed parts of the mesonephric ducts (mesoderm).

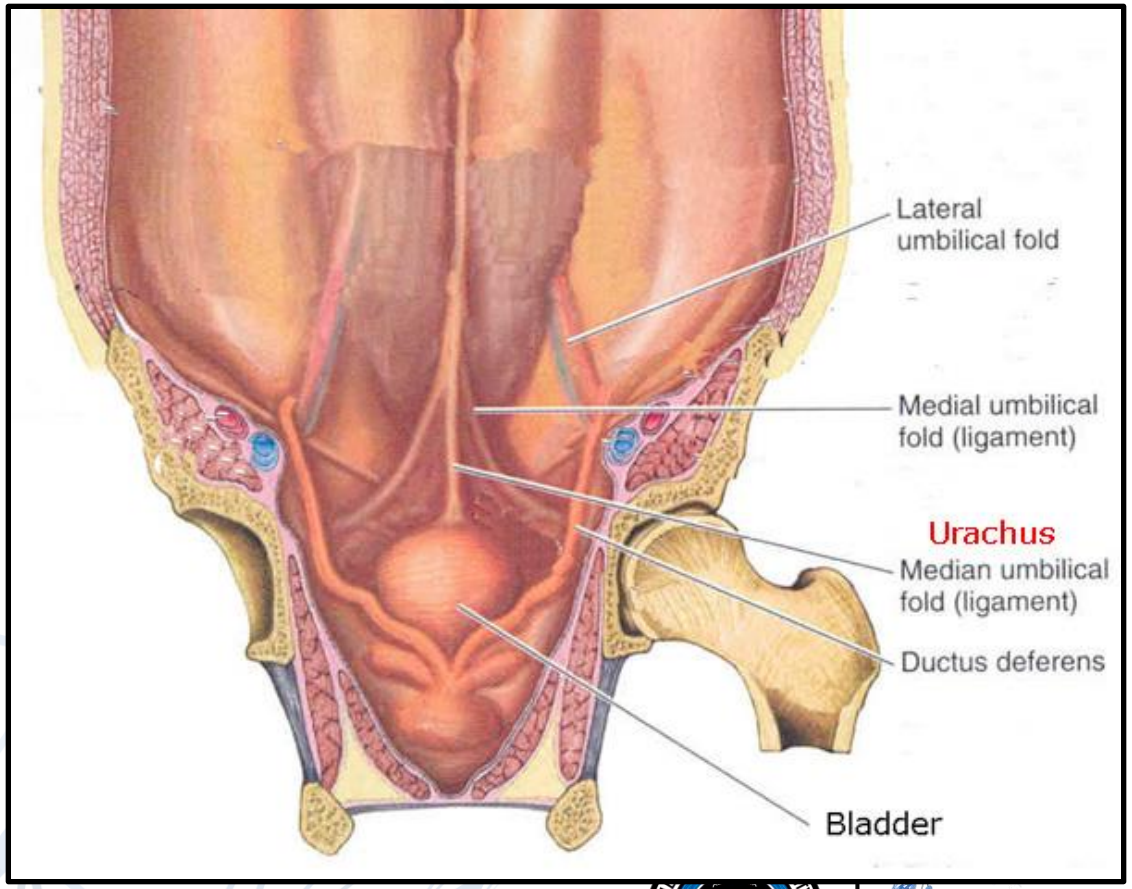

- **The muscle layer** develops from the surrounding splachnic mesoderm.

- At birth, the urinary bladder is an abdominal organ. It becomes a pelvic organ at puberty.

Development of Urinary Bladder

- Initially, the bladder is continuous with the **allantois** which constricts and becomes a thick fibrous cord, the **urachus**. In adults, the urachus is represented by the **median umbilical ligament**.

Development of Urinary Bladder

-As the bladder enlarges, distal parts of the **mesonephric ducts** are incorporated into its dorsal wall. These ducts contribute to the formation of the **trigone of the bladder**.

-As these ducts are absorbed, the ureters open separately into the urinary bladder.

- Partly because of traction exerted by the kidneys as they ascend, the orifices of the ureters move superolaterally and enter obliquely through the base of the bladder; those of the mesonephric ducts move close together to enter the prostatic urethra and in the male become the ejaculatory ducts. In females, the distal ends of the mesonephric ducts degenerate
